Routing fabrics logic block

Routed segment

Glitches

Dynamic power

Average net delay

Abstract

In this paper we created a new routing fabric for reducing power and delay. The power consumed in a FPGA core consists of both static and dynamic components. Static power contributes only 10% of the total power consumed in a FPGA. On the other hand, dynamic power contributes over 90% of the total power consumed and it is the main source for their power inefficiency. By reducing net length and /or programming overhead the power consumption reduced. Routed net length reduced by using short intersects segments in the routing channels. By decreasing the switch box and / or connection box flexibilities programming overhead reduced. In this work ,we concentrated on achieving 1.80 times lower consumption of dynamic power and 1.50 times less significant average net delays by re-architecting the programmable routing fabrics such that both routed net lengths and programming overhead reduced without adversely affecting delay.

1. Introduction

Power consumption is an important factor of designing integrated circuits .FPGA are much less power efficient when compared with cell-based ASIC. This power inefficiency limited application of FPGA in low power area. But FPGA has advantage that well suited to changing need and short design cycles. Hence reducing power consumption is important in FPGA. Dynamic power consumption caused by signal alteration. Higher operating frequencies lead to increased transistor activity which means more dynamic power Dissipation. The largest source of dynamic power Consumption in a FGPA is from charging and discharging capacitor

Signal transitions which directly determine dynamic power classified into two types they are functional transition and spurious transitions or glitches. Functional transitions occur when there is a transition needed to do

the logic function between two successive clock cycle. Glitches is short duration electrical pulse, usually it produces fault result particularly in a digital circuit. In FPGA, glitch power plays a major role of total dynamic power. Hence reducing glitches is important.

In this paper, we concentrated on reducing glitch power by balancing the path to inputs of look up table. So that signals of the same Look Up Table arrive at the same time and no glitches generated. Here we finding an alternative routes for early arriving signals so that the delays of the new routes causes the signals to arrive at the balanced times.

2. Related Work

Several techniques proposed to shrink power and Delay which includes

TORCH

TORCH based on simulated annealing procedure to find an optimized segmentation based on an average delay-power product. In each iteration, segmentation is incrementally changed, for new segmentation the benchmark designs routed into the FPGA using Versatile place route, the performance metric restructured, and the new segmentation is either accepted or rejected. Because of infrequent placements, Run time is much condensed. TORCH outputs have an optimized mix of track segment lengths and an ordering of the segmented tracks in the channel [2].

Timing-Driven routing algorithm

Every net in the circuit are repeatedly rips-up and re-routed, and gradually resolves routing congestion by gradually increasing the cost of overused routing resources. The slack of each connection used to decide the congestion avoidance delay minimization trade-off to use for that connection[5].

Versatile place route algorithm

The inputs to versatile place route consist of a technology routed net list and a text file describing the FPGA architecture. Versatile place route can place a pre-existing placement, or the circuit. Versatile place route can then do either a global route or a detailed route of the placement. Versatile place route output consists of the placement and routing, as well as statistics details useful in assessing utility of a FPGA architecture, which includes routed wire length, track count, and largest net length [3, 4].

Voltage scaling algorithm

It has two types of routing tracks based on consumption of voltage: High tracks and Low tracks. Both tracks are differs from using switches. High tracks get high supply voltage and faster than the low tracks. The paths having zero values can use the faster High tracks and the other paths can use the slower .Low paths to save power [4].

Congestion/Delay algorithm

Initially, nets routed one at a time using the shortest path by considering interconnect segment or logic block pin overuse. Each iteration of the router consists of

sequential net rip-up and reroute according to the lowest cost path available. The cost of using a routing resource is a current overuse and any overuse that occurred in preceding routing iterations. By gradually increasing the cost of an oversubscribed routing resource, the algorithm forces nets with alternative routes to avoid using that resource, leaving it to the net that most needs it[1].

Above discussed algorithm analyzed only the channel segments and most of which not discussed about the power consumption of look up table. We propose a similar technique that targets FPGA power and Delay. In addition to that we concentrated on Glitch reduction which is major part of power consumption.

Summary of Our Contribution:

- We propose the new routing fabric for reducing overall power and delay with the help of short segment.
- Dynamic power reduced by reducing glitches through path balancing.
- We describe algorithm to find a shortest path between source nodes and sink node with desired delay.

The paper organized as follows section 2 provides new routing architecture .In section 3 we described the method of reducing the dynamic power. Section 4 we described about routing algorithm for finding shortest path and we concluded the paper in section 5.

3. Routing Fabrics For 2D FPGA

In new routing fabrics logic block merged and arranged in an array format with horizontal and vertical routing channel overlay. Routed net lengths reduced by using only short interconnect segment in the routing channels. The routing block provides connectivity for logic block inputs and outputs as well as that it integrate the functions of connection and switch boxes. The routing points used to

- I. Form local connections between neighboring logic blocks without going to channels.
- II. Connect routing block inputs and outputs to channel segments and Chain channel segments together to form longer segments without entering routing blocks.

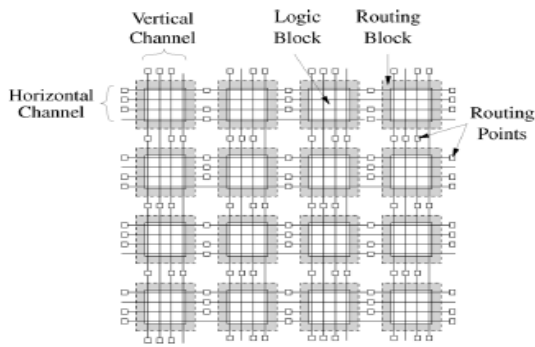

Figure 2. Modified 2D FPGA

3.1. Connection Between Logical Block And Routing Block

Routing block perform function of connection and switch boxes. Logical block comprises of look up tables, flip-flops and programming overhead. Every routing block can connect to n_i LB input such that each LB and routing block connected to bypass transistor switches. By choosing a value of n_i such that each LB input connect to the same number of routing block inputs. The loading on a routing block segment is lower than on a routing block input segment in the baseline fabric.

Figure 3. Logical block input & output connected to routing block

In addition to the connection through switch points, routing block architecture allows for extended switching width. In which a signal in a routing block looped back twice into it and exit to a perpendicular direction if it cannot do so directly. This extended switching much improves the efficiency of routing.

3.2. Connection Between Routing Block And Routing Channel Overlay

Every routing channel comprises of single and double segmented tracks. This segment has two unidirectional wires. The input and output connected by channel segment using the routing points. Segments joined together to form a longer segments, which called bypass interconnect. The segments can also be connected via routing points to routing blocks to connect to LB inputs and outputs, make bends, or fan-out.

Two types of net connections: Local and bypass connection. In local connection output of LB are already routed inputs of its neighboring LB without using routing channel segment. In order to route a longer net without entering intermediate routing block.

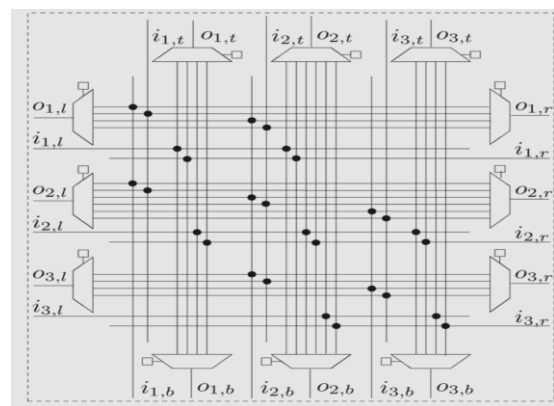

Figure 4. Routing Block

Figure 5.a and Figure 5.b shows the by-pass connection implementation. The resource sharing increases ability of routing. In addition to that it will also decrease the reloading on by-pass interconnect note that buffers alone turned on. This again reduces the loading on the connection, thus power consumption and its delay reduced.

Figure 5. (a) local interconnect and (b) by-pass interconnect

4. Dynamic Power Consumption

In FPGA, glitches generated at the output of a LUT when signals transition takes place at different times. The pulse width of these glitches depends on how uneven the

input signal arrival times are. Due to the limited connectivity of FPGA routing resources FPGA glitches are wider than ASIC glitches.

We avoided the glitches by adding programmable delay elements within the logic blocks of the FPGA such that we delay the early arriving signals to align the edges on each LUT input signals, thereby reducing some glitches on the output of each LUT. The method demonstrated in figure 6 by delaying the input signal of c, the output glitches eliminated since only the early arriving signals delayed, the overall critical path of the circuit is not increased.

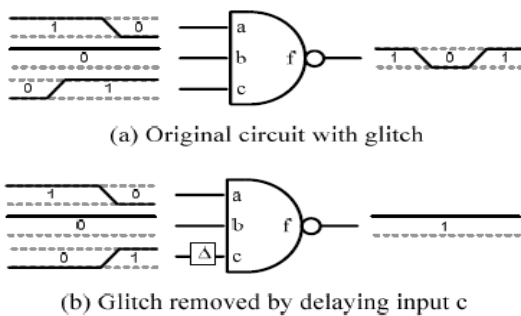

Figure 6. Removing Glitches by delaying early arriving signal

4.1. Programmable Delay Element

The delay element circuit consists of two inverters. The first inverter composed of pull-up and pull-down resistor for controlling the delay of the circuit. The second inverter has large channel lengths to decrease short-circuit power. Both pull-up and pull-down resistor have n stages with a resistor and a bypass transistor which controlled by an SRAM bit. Control bits used to double the value of resistor in later stages.

The control bit planned to produce any delay

$$\Delta \in \{k, \tau + k, 2\tau + k, 3\tau + k, \dots, (2n-1)\tau + k\}$$

Where τ is the delay produced by a resistor R to charge or discharge the capacitor C and k is the delay produced by the delay produced by the bypass resistances and inverters.

Figure 7: Programmable delay elements

5. Routing Algorithm For Reducing Delay

Initially without considering interconnect segment or logic block pins, nets routed one at a time using the shortest path. Several iterations carried out for finding shortest path. According to the lowest cost path nets are ripping up and rerouted at each iterations. The cost of mapping resource is function of its current overuse and any overuse that occurred in preceding mapping iteration. If the resources overused then algorithm forces nets with alternative routes to avoid using that resource.

Figure 8 shown below is the placing route graph for routing block. Here each routing block input signal and output represented by node. When routing algorithm applied to the routing graph shown below obtained. Figure 8 shows the shortest path between the source n_1 and n_2 . Solid line represents the direct connection and dashed line represents the extended connection

Figure 8. Routing graph for routing block

- C_{ij} is critical connection from the source of net i to one of its sinks j;
- I_d is the intrinsic delay of routing node n;
- P_c is the present congestion cost of node n.

Mobbing/Deferralevasion Algorithm

- 1: $C_{ij} \leftarrow 1$ for each signal net i and each sink j
- 2: **while** shared routing nodes exist **do**
- 3: **for all** nets i **do**
- 4: rip up routing tree RT_i
- 5: initialize the queue PQ
- 6: **for all** sinks t_{ij} **do**
- 7: enqueue each node n in RT_i at costs $C_{ij} I_d$ to PQ
- 8: **while** t_{ij} is not found **do**
- 9: dequeue node m with the lowest cost from PQ
- 10: **for all** fanout node n of m **do**
- 11: **if** node n is unseen **then**
- 12: mark node n as seen
- 13: enqueue n to PQ with the cost of $C_{ij} I_d + (1 - C_{ij}) I_d P_c$
- 14: **end if**
- 15: **end for**
- 16: **for all** node n in the routed path t_{ij} to s_j **do**

```

17:   update the cost of node n
18:   add n to RTi
19:   end for
20: end while
21: end for
22: mark all nodes in PQ as unseen
23: update Cij for net i
24: end for
25: end while
    
```

6. Comparison

Figure.9 show that the power consumption based on four technology nodes, and that the delay ratio increases with increase in technology nodes. This is because of increase in the parasitic wires.

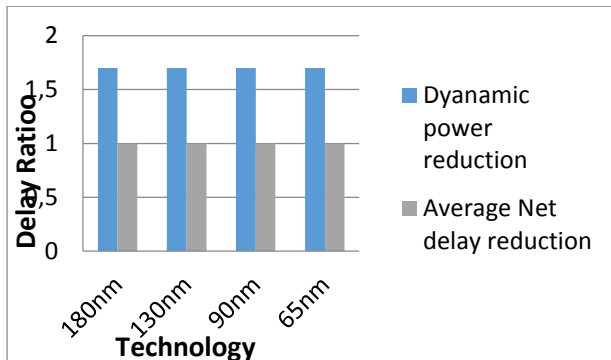

Figure9: Technology generation versus delay ratio

Figure 10 and Figure 11 shows the comparison of existing and proposed algorithm which results in the positive way.

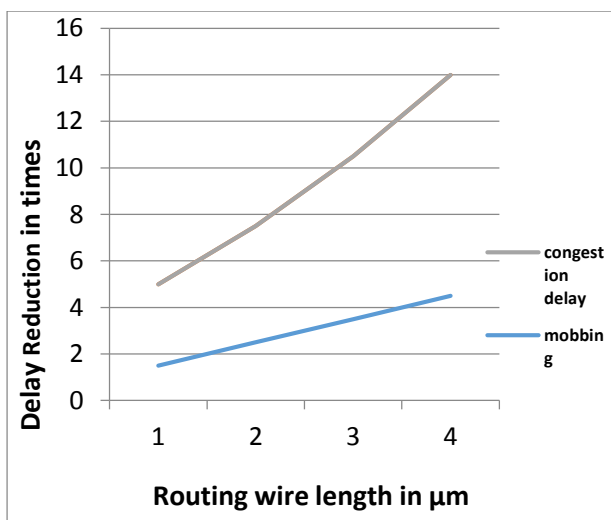

Figure10: Delay reduction

Figure11: Power Reduction

7. Conclusion

The power inefficiency of FPGA is a major problem. By reducing routed net length and programming overhead the power consumption reduced. Routed net length reduced by inter connect the segments by shortest routing channels. By decreasing the switch box and connection box flexibilities programming overhead reduced. We developed a new routing fabrics and algorithm FPGA can do 1.80 times reduction in the overall dynamic power consumption and 1.50 time reduction in average net delays.
